Life in Extreme Heat

The hydrothermal features of Yellowstone are magnificent evidence of Earth’s volcanic activity. Amazingly, they are also habitats in which microscopic organisms called thermophiles—“thermo” for heat, “phile” for lover—survive and thrive.

Grand Prismatic Spring at Midway Geyser Basin is an outstanding example of this dual characteristic. Visitors marvel at its size and brilliant colors. The boardwalk crosses a vast habitat for thermophiles. Nourished by energy and chemical building blocks available in the hot springs, microbes construct vividly colored communities. Living with these microscopic life forms are larger examples of life in extreme environments, such as mites, flies, spiders, and plants.

For thousands of years, people have likely wondered about these extreme habitats. The color of Yellowstone’s superheated environments certainly caused geologist Walter Harvey Weed to pause, think, and even question scientists who preceded him. In 1889, he (Weed, 1889) wrote:

*There is good reason to believe that the existence of algae of other colors, particularly the pink, yellow and red forms so common in the Yellowstone waters, have been overlooked or mistaken for deposits of purely mineral matter.*

However, he could not have imagined what a fantastic world exists in these waters of brimstone. Species, unseen to the human eye, thrive in waters as acidic as the liquid in your car battery and hot enough to blister your skin. Some create layers that look like molten wax on the surface of steaming alkaline pools. Still others, apparent to us through the odors they create, exist only in murky, sulfurous caldrons that stink worse than rotten eggs.

Today, many scientists study Yellowstone’s thermophiles. Some of these microbes are similar to the

---

**Words to Know**

- **Extremophile:** A microorganism living in extreme conditions such as heat and acid, that cannot survive without these conditions.
- **Thermophile:** Heat-loving extremophile.
- **Microorganism:** Single- or multi-celled organism of microscopic or submicroscopic size. Also called a microbe.
- **Microbes in Yellowstone:** In addition to the thermophilic microorganisms, millions of other microbes thrive in Yellowstone’s soils, streams, rivers, lakes, vegetation, and animals. Some of them are discussed in other chapters of this book.
- **Bacteria (Bacterium):** Single-celled microorganisms without nuclei, varying in shape, metabolism, and ability to move.
- **Archaea (Archaeon):** Single-celled microorganisms without nuclei and with membranes different from Bacteria. Once thought to be Bacteria.
- **Viruses:** Non-living parasitic microorganisms consisting of a piece of DNA or RNA coated by protein.
- **Eukarya (Eukaryote):** Single- or multi-celled organisms whose cells contain a distinct membrane-bound nucleus.
Thermophiles in the Tree of Life

Yellowstone’s hot springs contain species from the circled groups on this Tree of Life. Jack Farmer conceived of this version of the tree of life, which first appeared in *GSA Today*, July 2000 (used with permission).

The tree represents a simplified depiction of the evolutionary relationships among the three domains of life: Bacteria, Archaea, and Eukarya. It highlights the diversity of microorganisms found in hot environments, including those in Yellowstone. The different branches represent various groups of microorganisms, each adapted to specific environmental conditions.

**About Microbes**

Other life forms—the Archaea—predated Cyanobacteria and other photosynthesizers. Archaea can live in the hottest, most acidic conditions in Yellowstone; their relatives are considered among the very earliest life forms on Earth.

Yellowstone’s thermophiles and their environments provide a living laboratory for scientists, who continue to explore these extraordinary organisms. Researchers know that many mysteries of Yellowstone’s extreme environments remain to be revealed.

**Relevance to Yellowstone**

Among the earliest organisms to evolve on Earth were microorganisms whose descendants are found today in extreme high-temperature, and in some cases acidic, environments, such as those in Yellowstone. Their history exhibits principles of ecology and ways in which geologic processes might have influenced biological evolution.

Regardless of scientific advances, visitors and explorers in Yellowstone can still relate to something else Weed (Weed, 1889) wrote about Yellowstone, more than a century ago:

*The vegetation of the acid waters is seldom a conspicuous feature of the springs. But in the alkaline waters that characterize the geyser basins, and in the carbonated, calcareous waters of the Mammoth Hot Springs, the case is otherwise, and the red and yellow tinges of the algae combine with the weird whiteness of the sinter and the varied blue and green of the hot water to form a scene that is, without doubt, one of the most beautiful as well as one of the strangest sights in the world.*

Thermophilic Bacteria

The word “Bacteria” is often associated with disease, but only a few kinds of Bacteria cause problems for humans. The other thousands of Bacteria, although all simple organisms, play a complex role in Earth’s ecosystems. In fact, Cyanobacteria were responsible for the oxygenation of our atmosphere. They were the first photosynthesizers, converting light energy into oxygen more than 2.4 billion years ago. Without Bacteria, in particular Cyanobacteria, humans would not be here.

While some Bacteria perform photosynthesis, others depend on chemical energy that is released when compounds like hydrogen or sulfur react with oxygen. This energy is then used to convert carbon dioxide into biomass (chemosynthesis). For example, *Thermus* sp. may also be able to oxidize arsenic into a less toxic form.

Individual Bacteria may be rod or sphere shaped, but they often join end to end to form long strands called filaments. These strands help bind thermophilic mats, forming a vast community or miniecosystem. Other groups of Bacteria form layered structures resembling tiny towers, which can trap sand and other organic materials.

Archaea are the most extreme of all extremophiles, and some scientists think they have not changed much from their ancestors. Grand Prismatic Spring at Midway Geyser Basin contains archaea.

**Thermophilic Archaea**

Archaea are the most extreme of all extremophiles—some kinds live in the frigid environments of Antarctica; others live in the boiling acidic springs of Yellowstone. These single-celled organisms have no nucleus but have a unique, tough outer cell wall. This tough wall contains molecules and enzymes that may keep acid out of the organism, allowing it to live in environments of pH 3 or less. (For example, most vinegar has a pH of less than 3.) Archaea also have protective enzymes within their cells to keep them from becoming too acidic.

Some scientists think present-day Archaea have not changed much from their ancestors. This may be due to the extreme environments in which they live, which would allow little chance for successful changes to occur. If this is so, modern Archaea may not be much different from the original forms—and thus may provide an important link with Earth’s earliest life forms.

Once thought to be Bacteria, organisms in the domain Archaea actually may be more closely related to Eukarya—which includes plants and animals.

Many kinds of Archaea live in the hydrothermal waters of Yellowstone. For example, Grand Prismatic Spring at Midway Geyser Basin contains Archaea. They are most well known in the superheated acidic features of Norris Geyser Basin and in the muddy roiling springs of the Mud Volcano area.

Whenever you see a hot, muddy, acidic spring, you are probably seeing the results of a thriving community of archaeal cells called *Sulfolobus*. This is the archaon most often isolated and most well known by scientists. In sulfuric hydrothermal areas, it oxidizes sulfur into sulfuric acid, which helps dissolve the rocks into mud. The *Sulfolobus* community in Congress Pool (Norris) is providing interesting new research directions for scientists: It is parasitized by viruses never before known on Earth.

THERMOPHILES

Plants, animals, and mushrooms are the Eukarya most of us know. However, millions of unseen, microscopic members of this kingdom exist throughout our world, including in the extreme environments of Yellowstone.

Norris Geyser Basin is one of the best places to see thermophilic algae. Bright green *Cyanidioschyzon* grows on top of orange-red iron deposits around Whirligig and Echinus geysers and their runoff channels. Waving streamers of *Zygogonium* are especially easy to see in Porcelain Basin, where their dark colors contrast with the white surface.

From the boardwalk crossing Porcelain Basin, you can also see larger Eukarya, such as ephydrid flies. They live among the thermophilic mats and streamers, and eat algae, among other things. The species that lives in the waters of Geyser Hill, in the Upper Geyser Basin, lays its eggs in pink-orange mounds, sometimes on the firm surfaces of the mats. Part of the thermophilic food chain, ephydrid flies become prey for spiders, beetles, and birds.

Some microscopic Eukarya consume other thermophiles. A predatory protozoan called *Vorticella* thrives in the warm, acidic waters of Obsidian Creek, which flows north toward Mammoth Hot Springs, where it consumes thermophilic bacteria.

Thermophilic eukarya include one form that is dangerous to humans: *Naegleria*, a type of amoeba that can cause disease and death in humans if inhaled through the nose.

Although they aren’t visible like mushrooms, several thermophilic fungi thrive in Yellowstone.

Although they aren’t visible like mushrooms, several thermophilic fungi thrive in Yellowstone.
Curvularia protuberata lives in the roots of hot springs panic grass. This association helps both organisms survive higher temperatures than each could alone. In addition, researchers have recently discovered a virus inside the fungus that is also essential to the grass’s ability to grow on hot ground.

Of all the thousands, if not millions, of thermophilic species thriving in Yellowstone’s extreme environments, the Eukarya are the group that bridges the world of thermophilic microbes with the larger life forms—such as geese, elk, and bison—that thrive in ecological communities beyond the hot springs.

Thermophilic Viruses

Like Bacteria, the word “virus” often conjures up images of sickness and death. However, relatively few of the many types of viruses cause problems for humans. None of the thermophilic viruses in Yellowstone should cause problems for human health—our bodies are too cold, for one thing.

Unlike microorganisms in the three domains, viruses are not considered to be alive, yet they are still called “life forms.” They have no cell structure, only a protein “envelope” that encloses genetic material. They cannot reproduce on their own. Instead, a virus inserts itself into a host cell and uses that cell’s nutrients and metabolism to produce more viruses.

Scientists suspect many viruses exist in Yellowstone’s hydrothermal features because they would be a logical part of the thermophilic ecosystem. One kind was discovered in Congress Pool, at Norris Geyser Basin. It was infecting the archaean Sulfolobus. Another kind of virus has been identified in pools near Midway Geyser Basin.

Thermophilic Communities

Thermophilic communities are as diverse as the communities that humans live in. Community formations, colors, and locations vary depending on the types of microbes, the pH, and the temperature of their environments. Here, we discuss the microbe communities most easily seen in Yellowstone.

Millions of individual microbes can connect into long strands called filaments. Some Bacteria and algae form thin and delicate structures in fast moving water such as the runoff channels of hot springs and geysers. Other microbes form thick, sturdy structures in slower water or where chemical precipitates quickly coat their filaments.

A bacterium called *Thermocrinis* forms structures and is descended from ancient Bacteria that metabolized hydrogen and oxygen. Its filaments entwine, forming mats. Flowing water carries other microbes, organic matter, and minerals that become caught in the streamers and add to the mat.

Photosynthetic activity of Cyanobacteria such as *Lyptolyngbya* form columns or pedestals. Oxygen bubbles rise in the mat, forcing the microbes upward. The higher formations capture more organic matter and sediment than the lower mats, which help build the columns. Called stromatolites or microbialites, these structures are similar to ancient microbial communities preserved in formations around the world.

Mats can be as thin as tissue paper or as thick as lasagna. Multiple layers of microorganisms make up inch-thick mats. Dozens of types of microbes from all three domains can exist in these layers. Each layer is a community, and each layer interacts with the other layers, forming a complex, larger community full of millions of microorganisms and their life processes.

Changes in Communities

Visible and invisible changes occur in thermophile communities as light, temperature, and chemical concentrations change—both short term (within one day) and long-term (seasonally). As day brightens to noon, Cyanobacteria sensitive to light may move away from the surface; microbes less sensitive to light may move to the top layers of the mat. When light levels cause shifts in organisms, the community is responding to a light gradient.

Temperature and chemical gradients most often affect thermophilic communities in runoff channels of geysers and in shallow outflows from hot springs. The runoff channels from Pinwheel and Whirligig geysers meet. The outer edges of both are too hot for visible thermophile communities to develop. But as Pinwheel’s water cools in the shallower channel edge, *Cyanidium* (an alga) can grow, forming a bright green community. Whirligig’s runoff is hotter, which prevents *Cyanidium* from

Thermophilic community inhabitants are controlled, in part, by water temperature and pH. The chart provides general guidelines for maximum for each type.
Growing, but another type of thermophile thrives by oxidizing the abundant iron in the water, thereby forming the orange/red colored community.

At the Chocolate Pots, which you can see from pullouts along the Gibbon River just north of Gibbon Meadows, iron-rich water flows from the vents. Cyanobacteria—such as *Synechococcus* and *Oscillatoria*—thrive in this feature. The bacterial filaments form mats, in which orange-red iron oxide (rust) is captured. The iron may also be caught on the Bacteria as the microbes move about within the mat. An olive green color indicates where the orange iron and green bacteria are enmeshed. Darker streaks indicate the presence of manganese. Scientists think that mixing of iron-rich waters with shallow

precipitation-derived waters creates the unique conditions that give rise to the large iron and manganese oxide mounds at Chocolate Pots. These formations are not commonly encountered in the park.

Communities formed by thermophilic microbes sustain communities of larger organisms within Yellowstone’s hydrothermal areas. These communities in turn affect even larger communities of the park’s mammals. For example, bison and elk find food and warmth on the less extreme edges of thermophilic environments in winter. In turn, coyotes, wolves, and bears seek prey in these areas—especially in late winter and early spring when bison and elk are weaker than at any other time of year.

Whether it’s the strike of a grizzly’s paw or a shift in heat beneath the Earth, these communities change through both common and strange processes. Biologists continue to discover more about the individuals involved in thermophilic communities, and ecologists follow the threads of these intricate webs.

**Thermophiles in Time and Space**

**To Mars—and Beyond?**
The hydrothermal features of Yellowstone and their associated thermophilic communities are studied by scientists searching for evidence of life on other planets. The connection is extreme environments. If life began in the extreme conditions thought to have been widespread on ancient Earth, it may well have developed on other planets with similar conditions—and these conditions might still exist today.

The chemosynthetic microbes that thrive in some of Yellowstone’s hot springs do so by metabolizing inorganic chemicals, a source of energy that does not require sunlight. Such chemical energy sources provide the most likely habitable niches for life on Mars or on the moons of Jupiter—Ganymede, Europa, and Callisto—where uninhabitable surface conditions preclude photosynthesis. Chemical energy sources,
along with extensive groundwater systems (such as on Mars) or oceans beneath icy crusts (such as on Jupiter’s moons) could provide habitats for life.

**Similar Signatures**

Thermophile communities leave behind evidence of their shapes as biological “signatures.” For example, at Mammoth Hot Springs, rapidly depositing minerals entomb thermophile communities. Scientists compare these modern signatures to those of ancient deposits elsewhere, such as sinter deposits in Australia that are 350 billion years old. These comparisons help scientists better understand the environment and evolution on early Earth, and give them an idea of what to look for on other planets.

Yellowstone National Park will continue to be an important site for studies at the physical and chemical limits of survival. These studies will give scientists a better understanding of the conditions that give rise to and support life, and of how to recognize signatures of life in ancient rocks and on distant planets.
